Current Opinion in Pediatrics 2010, 22:54–60

Purpose of review

Ice hockey is a fast-paced sport played by an increasing number of children and teens across the nation.

Recent findings

The risk of injury in youth hockey is high due to contact from body checking. Youth hockey programs need to educate players, coaches, and parents about the importance of knowing and following the rules as well as the dangers of body checking another player from behind.

Summary

In this article, we will present an overview of the types and rates of injuries that occur in ice hockey and then present a detailed review of hip/groin injuries that are commonly diagnosed in these athletes.

Keywords

femoroacetabular impingement, high ankle sprain, ice hockey, sports hernia

Curr Opin Pediatr 22:54–60

Introduction

Ice hockey is a collision team sport played by approximately 350 000 children and adolescents under the auspices of USA Hockey, Inc., the national governing body for amateur ice hockey [1,2]. More than 80 percent of over 35 000 registered teams play in the age classifications 18 and under, prompting the Youth Council of USA Hockey to emphasize the educational and recreational values of ice hockey [3**].

The risk for injury in youth hockey is high due to contact from body checking. Hockey-related fatality and injury rates are more than twice as high as those in football [4]. Overall, body checking/collisions are the greatest cause of injury, accounting for 31.7% of injuries, followed by stick-induced injuries (18.2%), puck (14.0%), boards (10.5%), and ‘no-contact’ injuries (8.8%) [5]. On average, contusions are the most commonly diagnosed injury (24.3%), followed by sprains (17.3%), lacerations (16.2%), strains (12.1%), and fractures (8.1%) [5]. In general, ‘above shoulder’ injuries are the most common in ice hockey (26.1%) and include concussions, lacerations, and dental injuries. These are followed by knee (13.1%), shoulder (12.6%), hip/thigh/groin (11.9%), and hand/finger injuries (6.9%; Table 1) [5]. An epidemiological study of high school hockey injuries revealed 75 injuries per 100 players during a single season. Contusions were the most common, but injuries to the head and neck accounted for 22% of all injuries [6]. In a study of college men’s ice

hockey in the United States, concussion (18.6%) was the most common injury, followed by knee medial collateral ligament sprains, acromioclavicular joint injuries, and ankle sprains [7].

In the 1960s, an alarming number of facial injuries in youth hockey players led to the mandatory use of helmets with a face mask [8]. The helmet–face mask combination was remarkably successful in virtually eliminating facial trauma, but led to an increase in the number of neck and spinal injuries, possibly due to the false sense of protection from serious injury [9]. Body checking contributes not only to the number of injuries sustained but also to their severity. In a study of 117 hockey players with spine or spinal cord injuries, the most common cause of such injury was a push or check from behind (by an opponent) that catapulted the player headfirst into the boards [8]. Nevertheless, collision is allowed in boys’ ice hockey at the Peewee level (11–12-year-olds), even though size and physical maturity differ considerably among boys less than 16 years of age. It has been shown that weight can range from 34 to 70 kg for Peewees (11–12-year-olds) and from 37 to 90 kg for Bantams (13–14-year-olds), which has a great potential for serious injury [10].

Since studies have shown that a high proportion of youth hockey injuries are attributable to checking and that limiting checking can reduce injuries, the American Academy of Pediatrics recommends body checking should not be allowed in youth hockey for children of

Table 1 Summary of common injuries sustained during ice hockey based on anatomic location

Injury location	Diagnosis
Head and face	Concussions
	Lacerations
	Dental fractures
Neck	Cervical spine fractures
Shoulder	Acromioclavicular sprain
	Clavicle fracture
	Shoulder dislocation
Elbow	Bursitis
Wrist and hand	Scaphoid fractures
	Ulnar collateral ligament sprain
	Lumbar paraspinous muscle strain
Back	Spondylolysis
Hip	Femoroacetabular impingement
	Adductor muscle strain
	Hip flexor strain
Thigh	Quadriceps contusion
Knee	Medial collateral ligament sprain
Ankle	High ankle sprain

15 years of age or less; good sportsmanship programs, such as the fair-play concept, have been shown to reduce injury and penalty rates and should be adopted for all levels of youth hockey; and youth hockey programs need to educate players, coaches, and parents about the importance of knowing and following the rules as well as the dangers of body checking another player from behind [11]. Despite these recommendations, hockey will remain a contact sport, and the ideal age to learn the skills associated with delivering and receiving body checks is unclear.

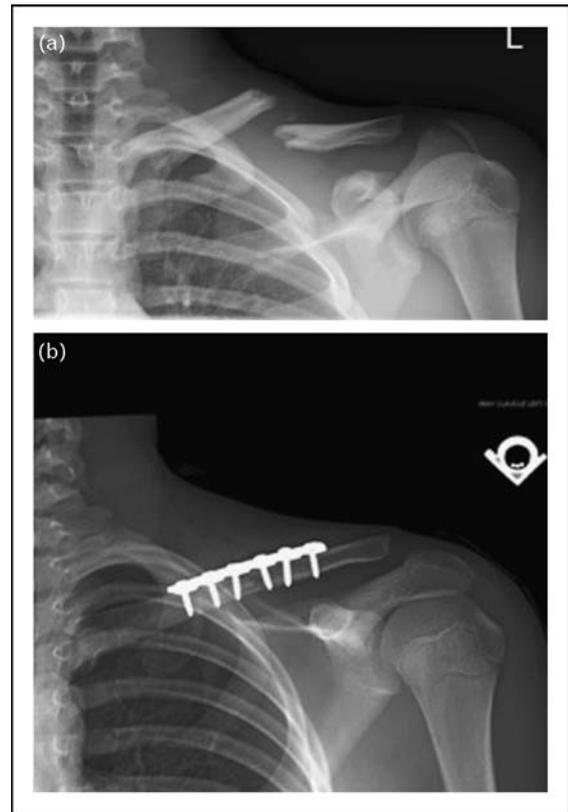

Upper extremity/shoulder

Injuries to the upper extremity in ice hockey are relatively common and serious. Body checking, contact with other players, striking against the boards, and blows by sticks are the usual mechanisms of injury. A direct blow to the shoulder can result in a clavicle fracture (Fig. 1a–b), acromioclavicular joint separation, or shoulder dislocation [12]. Elbow trauma may lead to fractures of the radial head, olecranon, distal humerus, or elbow dislocation. Injuries of the pediatric elbow can occur from a fall on an outstretched hand.

Gamekeeper’s thumb, rupture of the ulnar collateral ligament of the thumb, may occur when a player falls with the stick in hand. Molsa *et al.* [12] noted a high risk of fractures in players between 15 and 19 years of age, which may be explained by the increased velocity in skating, relative immaturity of bones, and increased body mass and strength.

The shoulder, elbow, and wrist have traditionally been considered well protected areas of an ice hockey player. However, shoulder pads in ice hockey are quite flexible and do not give the same protection as is provided by those used in American football. Hockey gloves have to

Figure 1 Serendipity views of a 14-year-old boy after sustaining a collision with another player

Serendipity views of a 14-year-old boy after sustaining a collision with another player demonstrating (a) a middle third displaced clavicle fracture. He underwent open reduction internal fixation (b) without complication.

be flexible in order to permit stick handling, so they are not able to prevent fractures such as distal radius fractures or scaphoid fractures, which are seen in hockey players.

Foot/ankle

Sprains of the ligamentous structures about the ankle have been established as one of the most common injuries in sports and a source of significant lost playing time for the athlete. In general, lateral ankle sprains are the most common type of injury [13]. The lateral ligamentous complex of the ankle consists of three ligaments: the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular ligament (PTFL). Clinical examination should include the anterior drawer test and talar tilt test to determine whether the ankle sprain is stable or unstable. The anterior drawer test is performed by securing the distal leg with one hand and applying an anterior pull on the heel with the foot held in gentle plantar flexion. Excessive anterior translation (>8 mm) or lack of a firm endpoint indicates a positive test [13]. If these tests are

negative, the ankle is considered to be stable and treatment can proceed in a symptomatic manner. If the ankle is classified as unstable, more aggressive treatment with some form of immobilization is warranted.

Another type of sprain that can occur involves the syndesmotom ligaments and the lay terminology for this injury is a 'high ankle sprain.' When the sprain results in a complete rupture of the ligaments, a diastasis can occur with separation of the distal ends of the tibia and fibula [14]. Syndesmosis sprains are a continuum of injury ranging from a minor sprain to frank diastasis [13]. High ankle sprains have been estimated to occur in as many as 1–18% of all ankle sprains [15–17]. High ankle sprains have received increased attention in the literature because many of these injuries go undiagnosed and are the source of chronic ankle pain and arthrosis in many patients. Calcification of the distal tibiofibular syndesmosis was reported in 32% of professional football players attending training camp, which suggests a much higher incidence of injury [18]. The squeeze test can be used to diagnose sprains of the tibiofibular syndesmosis and is performed by compressing the fibula and tibia proximal to the midpoint of the calf, which causes separation at the origin and insertion of the anterior inferior tibiofibular ligament. Although syndesmosis sprains are less common in sports than lateral ankle sprains (ATFL), several studies have demonstrated that syndesmosis sprains represent a significant injury in hockey players and, unlike in other sports, are a more common injury than lateral ankle sprains [7,19]. Thus, a high index of suspicion of high ankle sprains in hockey players is necessary. Creation of the syndesmotom injury by external rotation is unique to skiing and hockey because the ankle is constrained by a rigid ski boot or hockey skate. In addition, the elevation provided by the hockey skate blade, combined with high speeds and rapid direction changes, places the ankle at higher potential for torque injury, often related to 'catching a rut' in the ice with the skate blade.

Pelvis/hip

Groin pain is a common entity in ice hockey players. However, the cause of this pain may be difficult to elucidate because of the complex local anatomy and the multitude of differential diagnoses. In addition, the conditions responsible for groin pain are often insidious and diffuse with nonspecific presentations. To complicate matters even more, these athletes may also have more than one diagnosis that accounts for their symptoms, such as a player with a sports hernia and acetabular labral tear.

The most common musculoskeletal causes of chronic groin pain are adductor muscle strains and osteitis pubis [20]. Other causes of hip pain are included in Table 2

[21,22]. The pathologic entity known as sports hernia or athletic pubalgia is an occult hernia caused by a tear or weakness of the posterior inguinal wall, without a clinically recognizable hernia, which leads to a condition of chronic groin pain [23]. The exact incidence of sports hernia is not known, but several studies have demonstrated that it is quite common in athletes with recalcitrant groin pain despite nonsurgical treatment. Kluin *et al.* [24] found sports hernia to be the cause of chronic groin pain in 39% of their athletes based on diagnostic endoscopy. The most common physical findings include local tenderness over the pubic tubercle, conjoined tendon, and midinguinal region; a tender, dilated superficial inguinal ring; tenderness of the posterior wall of the inguinal canal; and pain with a resisted sit-up.

Table 2 Differential diagnosis of hip pain

Traumatic	Subluxation/dislocation Stress fracture/fracture Hematoma Contusion
Labral disorder	Femoroacetabular impingement Laxity Trauma Dysplasia
Infectious/tumor/ metabolic	Septic arthritis Osteomyelitis Benign bone and soft tissue neoplasms Malignant bone and soft tissue neoplasms Metastatic bone disease
Inflammatory	Rheumatoid arthritis Reiter's syndrome Psoriatic arthritis
Chondral disorder	Lateral impaction Avascular necrosis Loose bodies Chondral shear injury Osteoarthritis
Capsule disorder	Laxity Adhesive capsulitis Synovitis/inflammation
Nonmusculoskeletal causes	Psoas muscle abscess Spine Hernia Endometriosis Ovarian cyst Peripheral vascular disease
Unknown cause	Transient osteoporosis of the hip Bone marrow edema syndrome
Synovial proliferative disorders	Pigmented villonodular synovitis Synovial chondromatosis Chondrocalcinosis
Metabolic	Paget's disease Primary hyperparathyroidism
Extraarticular disorder	Coxa saltans (internal/external) Psoas impingement Abductor tears (rotator cuff tears of the hip) Athletic pubalgia Trochanteric bursitis Ischial bursitis Osteitis pubis Piriformis syndrome Sacroiliac disorder Tendonitis (hip flexors, abductors, adductors)

Obtained with permission from [22].

The physical examination is also extremely useful in determining the cause of chronic groin pain. A patient with a stress fracture usually has pain with axial loading of the leg. Pain and clicking with passive hip range of motion is suggestive of an acetabular labral tear. Pain with flexion, adduction, and internal rotations is suggestive of femoroacetabular impingement. Pain with resisted adduction and passive abduction of the thigh is suggestive of an adductor muscle strain. Pain with resisted hip flexion with tenderness to palpation over the rectus femoris suggests a rectus femoris strain. The patient with osteitis pubis usually has tenderness to palpation of the pubic symphysis.

Imaging

On the basis of the history and physical examination, various categories can be eliminated and the differential diagnosis further narrowed. The conventional radiograph then can provide a great deal of information and should include an anteroposterior radiograph of the pelvis, a Dunn lateral radiograph (90° flexion, 20° abduction), and a false-profile radiograph [25]. The anteroposterior radiograph of the pelvis should be carefully examined in order to exclude malalignment, impingement, subtle fractures, or evidence of dysplasia. A Dunn lateral radiograph is useful for identifying a cam lesion associated with femoroacetabular impingement (Fig. 2), and a false-profile radiograph (Fig. 3) is useful in evaluating coverage of the anterior portion of the femoral head.

Despite a thorough history and physical examination, it is oftentimes difficult to distinguish extraarticular from intraarticular pain. In nearly all patients with hip pain, a fluoroscopically or ultrasound-guided intraarticular injection of anesthetic medication is invaluable as a

Figure 2 Dunn lateral radiograph (elongated-neck lateral view) of the hip, demonstrating an osseous offset (yellow arrow) at the femoral head-neck junction, indicating a cam lesion

Figure 3 A false-profile view of the hip

This is a true lateral radiograph of the acetabulum, which allows measurement of coverage of the anterior portion of the femoral head (anterior center edge angle). A value of more than 25° is normal, whereas a value of 20° or less is consistent with acetabular dysplasia. (Obtained with permission from [21*]).

tool to determine whether the hip pain is due to disorder [26].

In most cases, an MRI is indicated to evaluate the acetabular labrum and articular cartilage, and to screen the pelvis for other causes of pain such as infection or tumor [27]. Evaluation of patients with osseous abnormalities can often be facilitated with a computed tomography scan with three-dimensional reconstructed images.

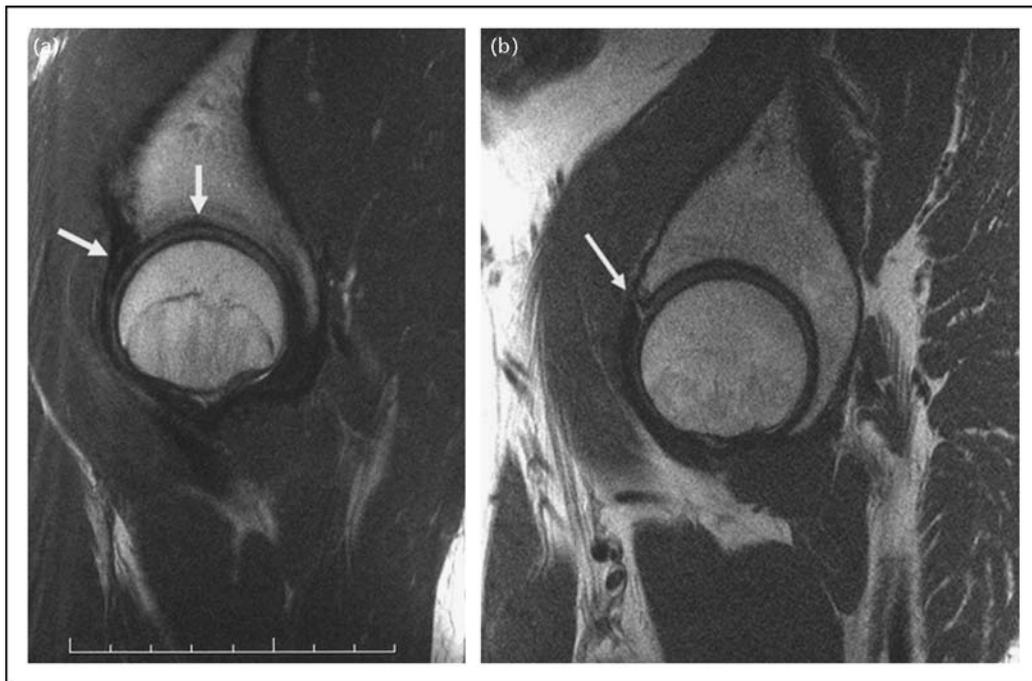

Labral tears

Injuries to the acetabular labrum are the most common pathologic findings identified during hip arthroscopy [28]. The labrum is a fibrocartilaginous structure that provides some structural resistance to vertical and lateral motion of the femoral head within the acetabulum and has an important sealing function that limits fluid expression from the joint space to protect the cartilage layers of the hip [29,30]. Mechanical symptoms and restricted range of motion are usually present with labral tears. Patients with clinical signs, magnetic resonance findings consistent with a labral tear (Fig. 4a–b), and persistent hip pain despite nonsurgical management are candidates for hip arthroscopy.

Femoroacetabular impingement

Two distinct types of femoroacetabular impingement (FAI) have been described, cam and pincer [31]. Cam

Figure 4 Sagittal fast spin echo MRI of the hip

Sagittal fast spin echo (FSE) MRI of the hip showing (a) a normal anterior labrum (arrows) as a triangular focus of low signal and normal articular cartilage of the acetabulum. Sagittal FSE MRI scan of the hip showing (b) a nondisplaced anterior labral tear (arrow).

impingement is the result of an abnormally shaped femoral head, which contacts a normal spherical acetabulum, most commonly in hip flexion and internal rotation. When the aspherical head-neck junction of the femur enters the acetabulum, it displaces the labrum toward the capsule and applies disproportionate load to the adjacent articular cartilage of the acetabulum. This leads to chondral delamination and detachment of the labrum from the acetabular rim.

Pincer impingement involves an abnormal acetabulum with retroversion or overcoverage of the femoral head [30]. This retroversion or overcoverage causes impingement of the labrum between the acetabulum and the femoral neck, resulting in crushing, degeneration, and eventual ossification of the labrum (Fig. 5). Chondral injuries are generally less severe than in cam impingement.

It has been demonstrated that FAI is a major cause of hip pain, reduced range of motion, and decreased performance in the athletic population [22,32]. Such injuries are common in a broad range of sports, including hockey, ballet, football, and soccer. Athletes usually present with anterior groin pain exacerbated by hip flexion, and physical examination reveals the impingement sign (pain with flexion, adduction, and internal rotation).

Hockey player’s syndrome

Hockey player’s syndrome is a distant entity that is unique to elite hockey players and involves a tear of

Figure 5 Coronal fast spin echo magnetic resonance image of a patient with combined femoroacetabular impingement with a cam lesion (arrow) and ossification of a torn superior portion of the labrum (arrowhead) consistent with pincer-type impingement

Obtained with permission from [27].

the external oblique aponeurosis associated with inguinal nerve entrapment [33,34]. The pain is typically worse in the morning, during the slap-shot motion and during the first few strides of skating. The pain may radiate to the hip, scrotum, or back. Pain usually occurs on palpation of the superficial inguinal ring and a palpable gap may occasionally be felt in the external oblique aponeurosis as the supine patient elevates his or her head or actively flexes the hip against resistance. Imaging studies are usually negative. Surgical exploration is the only method currently available to confirm the diagnosis. Irshad *et al.* [33] reported the results of 22 professional hockey players diagnosed with this condition after the failure of conservative treatment. The athletes underwent open surgical repair consisting of ablation of the ilioinguinal nerve and repair of the external oblique aponeurosis with mesh reinforcement. Eighty-six percent of patients were able to continue at the professional level and 82% were pain-free at final follow-up.

Sports hernia

When no hernia is detected on physical examination but the history and physical findings are consistent with a sports hernia, then nonsurgical treatment with rest, anti-inflammatory agents, and stretching and strengthening exercises should be initiated. When symptoms persist for more than 3 months with nonsurgical treatment, then a referral to a general surgeon for open or laparoscopic herniorrhaphy should be considered [23]. In addition, treatment of a contracted or overdeveloped adductor muscle should not be neglected and adductor tenotomy combined with herniorrhaphy should be considered. Meyers *et al.* [35] performed open pelvic floor repair on 157 athletes with chronic groin pain with broad surgical reattachment of the inferolateral edge of the rectus abdominis with its fascial investment to the pubis and adjacent anterior ligaments. Twenty-three percent of patients also underwent combined adductor release and 97% of patients returned to their preinjury activity levels.

Conclusion

Ice hockey is a contact sport that involves body checking at the Peewee level. USA Hockey has placed a special emphasis on coaches properly teaching the skills necessary to legally body check an opponent without intimidation. In addition, the 'Heads Up Hockey' program has emphasized clean play and preventive medicine [36]. In ice hockey, there is a vast array of hip and pelvic problems that may affect an athlete and decrease performance. Sports hernia is increasingly being recognized as a common cause of chronic groin pain in athletes. Additional research is needed to clarify the role of differing training regimens and conditioning exercises that may help prevent these injuries.
